The list of Internet-Draft Shadow Directories can be accessed at http://www.ietf.org/shadow.html.

Abstract

A means of provisioning OATH shared secret OTP parameters based on the XKMS protocol is described. The techniques used may be extended to support XKMS registration of symmetric keys for other cryptographic protocols. It is hoped that publication of this note will allow others to make use of the same architectural approach as a starting point for future proposals.

This work is a joint effort by the members of OATH (Initiative for Open AuTHentication) to specify an algorithm that can be freely distributed to the technical community. The authors believe that a common and shared specification will facilitate adoption of two-factor authentication on the Internet by enabling interoperability commercial and open-source implementations.

1. Conventions used in this document

The key words "MUST", "MUST NOT", "REQUIRED", "SHALL", "SHALL NOT", "SHOULD", "SHOULD NOT", "RECOMMENDED", "MAY", and "OPTIONAL" in this document are to be interpreted as described in RFC-2119 [RFC 2119].

2. Requirements

We consider three specific use cases that are believed to be indicative of the situations in which the provisioning protocol might be employed. These use cases are intended to be illustrative rather than exhaustive. For example a token issuer that purchases a large number of tokens intending to re-initialize them before issue is likely to find that their particular situation is closer to the manufacturing use case than initialization before issue.

2.1 Use Cases

The provisioning protocol is designed to meet the needs of three principal use cases corresponding to initialization at three different stages in the token life cycle.

Direct Static Provisioning (Bulk initialization)

In most cases an OATH token will be initialized during manufacture. This is likely to be the case even if the purchaser of the token is likely to re-initialize the token on receipt. The Device Initialization Tool obtains one or more credentials from a Credential Issuer. These are then installed in the OTP devices by the manufacturing equipment (Figure 1).

![Figure 1: Bulk initialization Use Case]
ability to obtain credentials from multiple issuers at different
times. Both parties want to minimize partner specific configuration.

In a manufacturing environment reliability and throughput are
critical. A provisioning protocol that requires the manufacturing
machinery to perform complex or lengthy calculation is unacceptable.

Manufacturing environments are frequently hostile to network
communications and the ability to continue production during brief
network outages is generally considered essential.

Requirement: Standards based protocol for communication between
Device Initialization Tool and the Credential Issuer.
Requirement: Bulk initialization of multiple tokens
Requirement: Protocol must not require the manufacturing
equipment to perform complex or lengthy calculation

Hallam-Baker Expiring August 2006 Page 3
XKMS Provisioning of OATH Shared Secret Keys Feb. 2006

Inferred Requirement: Server generated keys

Issuance to OTA Provisioning Service:

The Credential Issuer supplies OATH authentication credentials to an
Over-the-Air (OTA) Provisioning Service operated by a external entity
(e.g., application service provider, mobile operator, or enterprise
customer), for subsequent delivery of individual credentials to end
user mobile devices. The provisioning service receives stores
credentials securely for future wireless download to the user device.

Requirement: Supports bulk (pre-ordered range of tokens) and on-
demand (real-time request/response) issuance.
Requirement: Allows token IDs to be assigned by either the
credential issuer or the provisioning service.

Administrator initialization before issue

While bulk initialization under controlled conditions during
manufacture is likely to meet the security needs of most applications
reliance on a pre-disclosed secret is unacceptable to some
circumstances, in particular tokens issued for classified government
use.

In such cases the token issuer requires the ability to remove all the
secret information installed on the token during manufacture and
replace it with secret keys established under conditions controlled
by the issuer.

It is however in most cases impractical for the administrator to
apply a physical marking to the token itself such as a serial number.
It is therefore necessary for the enrolment process to communicate
the token serial number to the provisioning service. Another
situation in which initialization before use is required is the case
where the OTP functionality is installed on a previously manufactured
device as software (Figure 2).

Administrator                                 Credential
Initialization   <----Standard Protocol --->     Issuer

|
|
|                Tool

Device

Figure 2: Initialization before issue Use Case
Requirement: Administrator Initialization Tool to communicate a token serial number or other physical indicata to credential issuer.
Requirement: Administrator Initialization Tool to agree new shared secret information with the credential issuer.
Requirement: Administrator to be able to demonstrate that the shared secret information in the token has been generated in compliance with security practices.
Requirement: Credential Issuer to be able to demonstrate that the shared secret information in the token has been generated in compliance with security practices.

Architectural Approaches

The manufacturing use case clearly points to the use of a provisioning protocol where the secret key material is generated by the provisioning service. This corresponds to ‘server generated keys’ in terms of XKMS.

While this approach may be appropriate in some after-issue situations it does not meet all the requirements identified in the after-issue use cases. These use cases suggest the need for the client to participate in the generation of the secret key material. This corresponds to a new mode of key generation that is at present only applicable to symmetric key protocols in which both the client and server make a verifiable contribution to the randomness of the shared secret.

2.2 Constraints

Existing open standards

Design, development and review of cryptographic security protocols is an expensive and time consuming business requiring access to limited resources. Use of existing open standards is preferred whenever possible and appropriate.

Constraint: The protocols chosen should be based on existing open standards wherever possible

Web Services compliant

Web Services are increasingly the platform of choice for network application protocols. In the case of a device

Constraint: The protocols chosen should be based on the Web Services architecture

Support low speed devices

Most of the devices used to enroll in the protocol are highly constrained offering minimal computation capability and communication bandwidth. The overhead involved in XML processing in particular is greater than these devices are typically capable of supporting.

Constraint: It should be possible for a low speed device to participate in the protocol even if it is not capable of supporting an XML processing stack.

PKI provisioning support

Combination tokens offer both OTP and PKI authentication. It is clearly desirable to allow provisioning of the PKI secret key and the OTP shared secret to be supported by a common infrastructure.
Constraint: The protocols chosen for provisioning the OTP shared secret should be capable of provisioning PKI secret keys.

3. The XKMS Key Registration Service Specification

The use cases and constraints are best met by an extension to the XKMS Key Registration Service Specification (XKRSS) [XKMS].

XKRSS is an open standard agreed by the World Wide Web Consortium. The XKMS protocol is a Web Service designed to support provisioning of secret keys for PKI in both end user and bulk manufacture applications.

3.1 Extension to Shared Secret Keys

From an architectural point of view the problem of provisioning a shared secret is very similar to the problem of provisioning a secret key for use with an asymmetric algorithm.

- The secret key material must be transported in a form which protects against disclosure to any third party.
- At the end of the protocol the secret material must be established at the client.
- The security of protocols in which the secret key is employed will depend on the secret being generated in an appropriately secure manner, in particular the use of a sufficiently random and un-guessable seed.

There are also important differences:

- When provisioning a shared-secret there is no 'public key' attribute to be considered.
- At the end of the protocol the secret key material must be established at the provisioning service.

3.2 Secret Key Identifier

The purpose of a PKI provisioning protocol is generally described in terms of binding a collection of attributes such as a certificate holder's name to the public key.

In a shared-secret architecture there is no public key to bind the attributes to. There is however a surrogate that serves the same function. When an authentication service receives a request to perform an authentication against a shared-secret an identifier must be provided to inform the registry which shared secret is to be used.

A shared-secret identifier is a name; the choice of name is arbitrary and semantics of the identifier are defined exclusively by the registry. A public key is not a name; the choice is not arbitrary as it must be the mathematical compliment of the private key itself.

3.3 Key Generation

The requirement to establish the shared-secret at the provisioning service has important consequences for the choice of key generation mechanism. In a PKI provisioning infrastructure the disclosure of the private key to the provisioning service is a design choice that is appropriate in some cases (e.g. escrow of encryption keys) and inappropriate in others (e.g. signature or authentication keys).

In a shared secret provisioning infrastructure the shared secret must
be disclosed to the provisioning infrastructure by definition, otherwise it has not been ‘shared’.

XKMS supports two modes of key generation, at the client and at the server. Server side key generation is primarily intended for bulk issue and applications where the key is to be escrowed. If the private key is not to be escrowed by the service it is generally preferable to generate it at the client and avoid the need to transport it over the network at all.

Server Side Key Generation

Bulk issue of shared-secret keys is no different in principle to bulk issue of PKI keys. The ability to use a single protocol to support both types of provisioning is clearly a benefit to manufacturers and issuers requiring bulk re-initialization. The only additional requirement needed to support provisioning of OATH shared secrets is to define an appropriate shared secret container.

Client Side Key Generation: Not applicable

The client side key generation protocol defined in XKMS does not meet the needs of shared-secret generation described in the use cases and does not appear to offer any benefit over server generated keys when a symmetric key algorithm is involved.

Mutual Key Generation

In a mutual key generation the client and service both contribute random material to the generated key. This allows both parties to ensure that the generated key is sufficiently random and un-guessable.

The key generation mechanism defined employs a Diffie-Hellman key exchange.

1. The client generates a random private key $c$ and calculates the corresponding public key $e$.
2. The client public key $e$ is communicated to the service.
3. The service generates a random private key $s$ and calculates the corresponding public key $e$.
4. The service calculates the shared secret $H(e^s)$.
5. The service public key $e$ is communicated to the client.
6. The client calculates the shared secret $H(e^c)$.

The established shared secret contains random information contributed by both the client and the service. The shared secret will be sufficiently random provided that one of the parties generated a sufficiently random private key.

Although the Diffie-Hellman key exchange is considered to be a secure public key exchange algorithm the security of the protocol against a disclosure attack requires both parties to choose a sufficiently random private key. The use of a secure transport protocol is therefore required.

4. XKRSS Profile

4.1 Identifiers

The following identifiers defined by external sources are used in...
http://www.w3.org/2002/03/xkms#  
XKMS Schema  
http://www.w3.org/2000/09/ xmldsig#  
XML Signature Schema  
http://www.w3.org/2001/04/xmlenc#DHKeyValue  
Diffie-Hellman key agreement

The following identifiers are defined and used in this document:  
urn:ietf:rfc:4226  
The OATH OTP specification

The following identifiers are defined and used in the Internet draft  
Portable Shared Secret Container [Container]  
http://www.openauthentication.org/2006/02/PSKC  
Schema used to encode the HOTP shared secret parameter values  
before encryption.

4.2  
SOAP Binding

Any of the bindings described in the document XML Key Management  
Specification (XKMS 2.0) Bindings may be employed by a compliant  
implementation.

The use of the following specific bindings is RECOMMENDED:  
SOAP Binding: SOAP 1.2, SOAP over HTTP binding  
Confidentiality Binding: SSL/TLS or WS-Security  
Authentication Binding: Payload authentication (if required)

The XKMS specification does not define a WS-Security binding as the  
design predates it. The use of WS-Security is preferred over TLS as  
it provides support for firewall infrastructure.

4.3  
Authentication Binding

The choice of payload authentication or a limited use shared secret  
for authentication is determined by the application:

  . Payload authentication using a pre-established public key is  
    preferred for bulk issue and administrative issue. Payload  
    authentication allows multiple registration requests to be  
    authenticated using a single signature.  
  . End-users cannot be expected to have an authentication mechanism  
    until after the registration process has been completed. In  
    these cases the KeyBindingAuthentication mechanism is  
    RECOMMENDED.

4.4  
Request

Prototype Key Binding

The prototype key binding contains information that the client  
requests be present in the keybinding resulting from the request.

A <KeyUsage> element MUST specify authentication (signature) as an  
authorized use: http://www.w3.org/2002/03/xkms#Signature
A `<RespondWith>` element MUST request that a Diffie-Hellman
http://www.w3.org/2001/04/xmlenc#DHKeyValue

A `<UseKeyWith>` element of the prototype key binding MUST specify the
use of the OATH OTP protocol: urn:ietf:rfc:4226.

The `<ds:KeyInfo>` element SHOULD contain a `<ds:KeyName>` element
contains an identifier for the token to be registered. This
identifier need not be a physical identifier present on the token but
will be the identifier used by the authentication service to identify
the token in an authentication request.
Administrators may make use of the `<ValidityInterval>` and
`<RevocationCodeIdentifier>` elements to provide additional control
over use of the token.

Additional Key Elements MAY be specified by including a portable key
container as defined by [Container] within the `<ds:KeyInfo>` element

A revocation code identifier is a self authenticating information
code that tells the provisioning service to revoke the corresponding
key binding. Use of the revocation code does not require either
authentication or a confidential channel to the provisioning service.
This allows a multi-function device to provide a means of securely,
reliably and verifiably terminating the validity of the key binding.
The shared secret MUST NOT be used as the revocation code. A one way
hash of the revocation code MAY be used.

Server Key Generation

A `<RespondWith>` value MUST specify that a private key value is
requested using the identifier
http://www.w3.org/2002/03/xkms#PrivateKey

Mutual Key Generation

A `<RespondWith>` value MUST specify that a request for a mutually
agreed key using the identifier: urn:ietf:rfc:4226

The `<ds:KeyInfo>` element of the `<PrototypeKeyBinding>` MUST include a
`<ds:KeyValue>` element that specifies the Diffie-Hellman public key
parameters of the client.

The requestor SHOULD specify a random value for the `<Data>` element.
The same value is returned in the encrypted Private key parameters in
the response allowing the requestor to verify that the value of the
key agreement generated at the server matches.

4.5
Response
Key Binding

The KeyBinding returned by the provisioning service must meet the
same constraints as the PrototypeKeyBinding specified in the request.

Server Key Generation

If the request is successful the `<PrivateKey>` element MUST be present
and MUST contain the encrypted OTP parameters encoded under the
schema described in [Container]

Mutual Key Generation

If the request is successful the `<ds:KeyInfo>` element of the returned
`<KeyBinding>` MUST include a `<ds:KeyValue>` element that specifies the
Diffie-Hellman public key parameters newly generated by the service.
The shared secret is derived by applying the Diffie-Hellman key agreement algorithm as specified in XML Encryption. The initial counter value is 0.

The <PrivateKey> element MAY be present and MAY contain the encrypted OTP parameters encoded under the schema described in [Container]. The result of the Diffie-Hellman key agreement replaces the value specified for the <Data> element if specified.

Appendix A: Example Messages (Non normative)

This section provides non-normative examples of using the registration protocol. For clarity the XKMS transport and message level security bindings are omitted.

A.1 Server Generated Key

This example meets the requirements set out in the 'bulk initialization' use case. A client at the manufacturing site makes a request for one or more private keys to be created and bound to a specified token identifier.

For efficiency authentication and encryption are performed in this particular instance using a pre-shared key. The pre-shared key might be established through out of band configuration or by means of a standard key agreement protocol. Alternatively public key protocols might be used for authentication and encryption.

The pre-shared key used for MAC generation and encryption is:
3n9cjk4jks04jfw0934jsr09jwik4

The algorithm specified in [XML-ENC] is then used to derive the value
for the token master secret:

Keying Material = KM(1) | KM(2) | ...
KM(counter) = DigestAlg (Shared Key | counter | EncryptionAlg | KeySize)

The value KA-Nonce is not used.

The string (counter | EncryptionAlg | KeySize) is:

The value of the token master secret is:
b20d1e4ffe796685d95340b33fdd6e695ba6a0
